Abstract. Dry deposition at the Earth's surface is an important sink of atmospheric ozone. Currently, dry deposition of ozone to the ocean surface in atmospheric chemistry models has the largest uncertainty compared to deposition to other surface types, with implications for global tropospheric ozone budget and associated radiative forcing. Most global models assume that the dominant term of surface resistance in the parameterisation of ozone dry deposition velocity at the oceanic surface is constant. There have been recent mechanistic parameterisations for air-sea exchange that account for the simultaneous waterside processes of ozone solubility, molecular diffusion, turbulent transfer, and first-order chemical reaction of ozone with dissolved iodide and other compounds, but there are questions about their performance and consistency. We present a new two-layer parameterisation scheme for the oceanic surface resistance by making the following realistic assumptions: (a) the thickness of the top water layer is of the order of a reaction-diffusion length scale (a few micrometres) within which ozone loss is dominated by chemical reaction and the influence of waterside turbulent transfer is negligible; (b) in the water layer below, both chemical reaction and waterside turbulent transfer act together and are accounted for; and (c) chemical reactivity is present through the depth of the oceanic mixing layer. The new parameterisation has been evaluated against dry deposition velocities from recent open-ocean measurements. It is found that the inclusion of only the aqueous iodide–ozone reaction satisfactorily describes the measurements. In order to better quantify the global dry deposition loss and its interannual variability, modelled 3-hourly ozone deposition velocities are combined with the 3-hourly MACC (Monitoring Atmospheric Composition and Climate) reanal-

ysis ozone for the years 2003–2012. The resulting ozone dry deposition is found to be $98.4 \pm 30.0 \text{ Tg O}_3 \text{ yr}^{-1}$ for the ocean and $722.8 \pm 87.3 \text{ Tg O}_3 \text{ yr}^{-1}$ globally. The new estimate of the ocean component is approximately a third of the current model estimates. This reduction corresponds to an approximately 20 % decrease in the total global ozone dry deposition, which (with all other components being unchanged) is equivalent to an increase of approximately 5 % in the modelled tropospheric ozone burden and a similar increase in tropospheric ozone lifetime.

1 Introduction

In the troposphere, the budget of ozone (O_3) is determined by its transport from the stratosphere, dry deposition at the Earth's surface, and chemical production and loss. Dry deposition is a significant sink of ozone (Galbally and Roy, 1980), influencing ozone mixing ratio, its lifetime, and long-range transport. The average dry deposition velocity of O_3 to the ocean is less than that to terrestrial surfaces, but because of the larger coverage of the Earth's surface by the oceans there is substantial dry deposition to water. A current estimate of total global dry deposition of O_3 is $1094 \pm 264 \text{ Tg yr}^{-1}$ (IPCC, 2013; Young et al., 2013), of which about 35 % is to the ocean (Ganzeveld et al., 2009; Hardacre et al., 2015). Hardacre et al. (2015) observed that ozone dry deposition to the water surface in models has the largest uncertainty compared to other surface types. A proper treatment of dry deposition to the ocean in atmospheric chemistry models is thus necessary for more accurate ozone estimates and better

representation of feedback cycles, e.g. that involving iodine chemistry (Carpenter et al., 2013). Although dry deposition of ozone to the ocean is the focus of the present paper, we also place ocean dry deposition in the context of total global dry deposition. In this paper the word deposition means dry deposition.

Dry deposition flux, F_{O_3} , of ozone to the surface is normally calculated as the product of its concentration, $[O_3]$, in the air near the surface and a (downward) dry deposition velocity, v_d :

$$F_{O_3} = v_d [O_3]. \quad (1)$$

A common approach to parameterising v_d is to express it as a linear sum of three resistances (e.g. Wesely, 1989):

$$v_d = \frac{1}{r_a + r_b + r_c}, \quad (2)$$

where the aerodynamic resistance r_a is the resistance to transfer by turbulent mixing in the atmospheric surface layer, the atmospheric viscous (or quasi laminar) sublayer resistance r_b is the resistance to movement across a thin layer (0.1–1 mm) of air that is in direct contact with the surface, and the surface resistance r_c is the resistance to uptake by the surface itself that can be controlled by physical, chemical, biological, or other processes depending on the surface type and the species of interest.

At this point it is useful to define the waterside layers near the sea surface that are relevant (Fig. 1). The top few millimetres of the sea surface is often termed the sea surface microlayer, which may be composed of various sub-layers or scales depending on the physical, chemical or biological properties being considered (Soloviev and Lukas, 2014; Carpenter and Nightingale, 2015). Very close to the water surface is a viscous sublayer (~ 1 mm) within which viscous processes dissipate the turbulent kinetic energy associated with the smallest of the eddies (of the size of Kolmogorov microscale) into heat. Thus the viscous sublayer thickness is of the order of the level at which the turbulent eddy diffusivity falls below the kinematic viscosity. A level exists within the viscous sublayer at which the diminishing eddy diffusivity falls below the molecular diffusivity, and this level is approximately the thickness of the diffusive sublayer ($\sim 50 \mu\text{m}$ for ozone). Embedded within the diffusive sublayer can be another sublayer (which we call the reaction–diffusion sublayer) characterised by chemical reactivity and molecular diffusivity, whose thickness is scaled by a reaction–diffusion length scale (typically $3 \mu\text{m}$ for the ozone–iodide reaction in water). In the surface turbulent layer (or mixing layer) (~ 10 –50 m) below the surface microlayer, turbulent processes dominate.

For ozone dry deposition to water surfaces, r_c is the dominant term in Eq. (2). It is commonly assumed that r_c for water is constant ($\approx 2000 \text{ s m}^{-1}$) based on Wesely's (1989) widely used deposition parameterisation, and to our knowl-

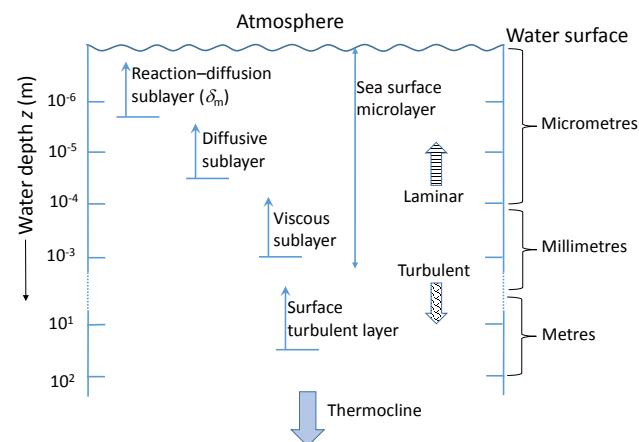

Figure 1. Idealised representation of the vertical structure of the top few metres of sea water. The depth of the reaction–diffusion sublayer (δ_m) will vary according to the chemical reactivity of the ocean water to ozone.

edge this approach is used by default in most global chemical transport models, e.g. MATCH-MPIC (von Kuhlmann et al., 2003), MESSy (Kerkweg et al., 2006), MOZART-4 (Emmons et al., 2010), CAM-chem (Lamarque et al., 2012), GEOS-Chem (Mao et al., 2013), and UKCA (Abraham et al., 2012).

Recently, Luhar et al. (2017) demonstrated that the use of a constant r_c for water results in a near-constant behaviour of v_d with sea surface temperature (SST) which overestimates the open-ocean deposition velocity measurements of Helmig et al. (2012) by as much as a factor of 2 to 4 for cooler SSTs. Luhar et al. (2017) also tested a mechanistic, one-layer reactivity scheme for r_c proposed by Fairall et al. (2007), which includes the influence of waterside processes acting on ozone, namely solubility, molecular diffusion, turbulent transfer, and a first-order chemical reaction of ozone with dissolved iodide, and they found that the one-layer scheme also overestimates the deposition velocity measurements (albeit to a slightly lesser degree than the constant r_c approach) due to an overestimation of turbulent (or eddy) diffusivity within the waterside viscous sublayer. Ganzeveld et al. (2009) included the one-layer scheme in a global model and found that compared to the Wesely constant r_c approach the one-layer scheme leads to only a slight reduction in the total oceanic deposition of ozone, which is consistent with the findings from the same one-layer scheme by Luhar et al. (2017).

Following Fairall et al. (2007), Luhar et al. (2017) formulated a two-layer reactivity scheme for r_c in which the chemical reactivity of ozone with dissolved iodide was assumed to be present only within the reaction–diffusion sublayer ($\delta_m \sim 3 \mu\text{m}$) with the water region below δ_m having a near-zero background chemical reactivity (through the assumption that the iodide concentration below δ_m was vir-

tually zero). This two-layer reactivity scheme when used in a global chemistry–climate model, namely ACCESS-UKCA (Australian Community Climate and Earth System Simulator – United Kingdom Chemistry and Aerosol), was able to describe the absolute magnitude and the sea surface temperature dependence of the deposition velocity measurements of Helmig et al. (2012) over the ocean well.

Although the two-layer reactivity scheme of Luhar et al. (2017) was successful in describing the observations, its assumption that chemical reactivity is only present within a depth of water that is of the order of only a few micrometres is arbitrary given that in reality iodide is present through the depth of the oceanic surface turbulent layer ($\sim 10\text{--}50\text{ m}$) and even deeper (Chance et al., 2014). The primary reason the two-layer reactivity scheme worked well was that limiting chemical reactivity to the reaction–diffusion sublayer artificially compensated for the effects of the overestimation of turbulent diffusivity (K_t) (see below) in this layer, thereby effectively restricting the vertical extent of the ozone–iodide reaction and its interaction with turbulence to the scale δ_m and thereby circumventing the overestimation of v_d .

The overestimation of K_t alluded to above in both one- and two-layer formulations results from the use of the linear parameterisation $K_t = \kappa u_{*w} z$, where u_{*w} is waterside friction velocity, κ is the von Karman constant ($= 0.4$), and z is depth from the surface. This parameterisation is valid for a fully turbulent surface layer that lies beyond the viscous sublayer. For depths within the viscous sublayer, the viscous dissipation of turbulence causes the eddy diffusivity to diminish much more rapidly with decreasing z than provided by the linear relationship above. A more appropriate parameterisation for K_t that varies as z^m in the viscous sublayer where $m = 2\text{--}3$ (Fairall et al., 2000) can be considered but a corresponding analytical solution for r_c that includes chemical reaction, molecular diffusion, and turbulent transfer has not so far been found.

The aims of the present paper are twofold. First, to formulate a new two-layer parameterisation for r_c that eliminates the assumption inherent in the (old) two-layer reactivity scheme that chemical reactivity is only present within the top few microns of the water surface. Instead the new scheme makes the valid assumption that chemical reactivity is present through the depth of the oceanic mixing layer, as supported by observations. The new scheme employs a plausible assumption with regards to the extent of reaction-dominated deposition regime and has an asymptotic behaviour that is consistent with the known limits when turbulent transfer dominates over chemical reaction and vice versa. This new scheme is incorporated into ACCESS-UKCA and the results on deposition velocity are compared with the data of Helmig et al. (2012) and other schemes.

Second, given that there are significant biases in global modelling for ozone in the lower atmosphere, one alternative to constrain ozone dry deposition budgets better is to use ozone reanalyses involving data assimilation, which are

taken as a more reliable source of near-surface ozone data than those obtained by models alone. By adopting this approach, the oceanic and global dry deposition budgets of ozone are estimated by combining the gridded global reanalyses for near-surface ozone from the European MACC (Monitoring Atmospheric Composition and Climate) program and the ozone deposition velocities estimated using the new two-layer oceanic deposition scheme in ACCESS-UKCA for 10 years (2003–2012). The interannual variability and uncertainty in these budgets are investigated and the latter are compared with those from other studies.

2 A new two-layer scheme for surface resistance r_c

Assuming horizontal homogeneity and stationarity, the mass conservation equation for a chemical species in water is (Geernaert et al., 1998; Fairall et al., 2007)

$$\frac{\partial}{\partial z} \left[\{D + K_t(z)\} \frac{\partial C(z)}{\partial z} \right] - a C(z) = 0, \quad (3)$$

where z is depth from water surface, $C(z)$ is the concentration of the species, D is the molecular diffusivity of the species in water, $K_t(z)$ is the turbulent diffusivity, and a is a first-order reaction rate coefficient which for the ozone–iodide reaction ($O_3 + I^- \rightarrow \text{products}$) is determined as the pertinent second-order rate coefficient (k) multiplied by the iodide concentration ($[I^-]$).

A flux variable F_0 (which we will just refer to as flux) that is invariant with water depth z can be defined by integrating Eq. (3) (Fairall et al., 2007):

$$-[D + K_t(z)] \frac{\partial C(z)}{\partial z} + a \int_0^z C(z) dz = F_0. \quad (4)$$

The first term on the left-hand side of Eq. (4) is the mixing flux (molecular diffusion plus turbulent mixing), which decreases with depth as the reacting gas is absorbed. This component is balanced by the second term on the left-hand side, which is the integrated loss rate of ozone by chemical reaction between the ocean surface and depth z .

We now consider an alternative two-layer approach in which chemical reaction in the top water layer of depth δ_m (i.e. the reaction–diffusion sublayer that is embedded within the viscous sublayer) is fast enough such that it dominates over turbulent transfer, with the assumption $K_t = 0$, and transport is maintained by molecular diffusion (Fig. 2). The thickness of this layer is thus of the order of the so-called reaction–diffusion length scale $l_m = (D/a)^{1/2}$ for the ozone–iodide reaction in seawater which is typically a few micrometres. This length scale for the said reaction is even smaller than the Kolmogorov microscale (the latter is indicative of the smallest of the turbulent eddies present in the flow) so it is fair to assume that $K_t = 0$ within the reaction–diffusion sublayer. The second layer, which is deeper than the reaction–diffusion sublayer (i.e. $z > \delta_m$), has both chemical reaction

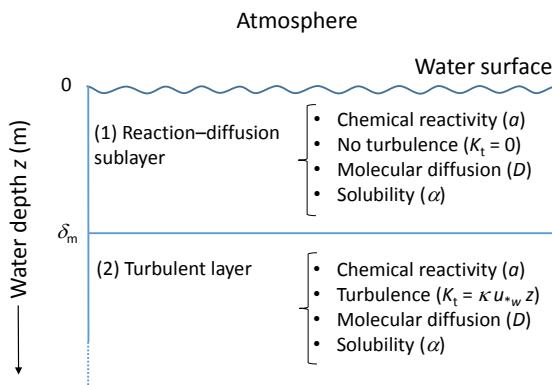

Figure 2. A simplified, two-layer structure used to represent the near-surface ocean in the model and the processes included in the calculation of ozone dry deposition to sea water.

and turbulent mixing included, and a linear parameterisation for turbulent diffusivity $K_t = \kappa u_{*w} z$ is used (Fig. 2). The second layer can thus include part of the viscous sublayer and extend to the surface turbulent layer. The chemical reaction of ozone predominantly occurs in the first layer. In the second layer, turbulence–chemistry interaction is weak compared to transfer by turbulent mixing. It is therefore reasonable to use a linearly varying K_t throughout the second layer. Both layers have the same reactivity a , i.e. the iodide concentration is uniform through the oceanic surface mixed layer. (In contrast to Fig. 2, the two-layer scheme of Luhar et al. (2017) assumed $K_t = \kappa u_{*w} z$ in both layers and $a \approx 0$ in the second layer. The one-layer scheme of Fairall et al. (2007) is equivalent to setting $K_t = \kappa u_{*w} z$ in both layers or $\delta_m \rightarrow 0$ in Fig. 2).

With the assumptions above, Eq. (3) can be solved for concentration (C_1) in the first (i.e. top) layer and that (C_2) in the second (i.e. bottom) layer to yield

$$C_1(z) = A_1 \exp\left(z\sqrt{\frac{a}{D}}\right) + B_1 \exp\left(-z\sqrt{\frac{a}{D}}\right), \quad (5)$$

$$C_2(z) = B_2 K_0(\xi), \quad (6)$$

where $\xi = [2ab(z + (bD/2))]^{1/2}$, $b = 2/(\kappa u_{*w})$, $\kappa = 0.4$, and $K_0(\xi)$ is the modified Bessel function of the second kind of order 0.

The expressions for the mixing component (which includes both turbulent and molecular diffusion parts) of the flux F_0 in the first and second layers follow from the first part on the left-hand side of Eq. (4) coupled with Eqs. (5) and (6):

$$F_{m1}(z) = \dots \quad (7)$$

$$\dots - (aD)^{1/2} \left[A_1 \exp\left(z\sqrt{\frac{a}{D}}\right) - B_1 \exp\left(-z\sqrt{\frac{a}{D}}\right) \right],$$

$$F_{m2}(z) = \frac{B_2}{b} \xi K_1(\xi), \quad (8)$$

where $K_1(\xi)$ is the modified Bessel function of the second kind of order 1.

The three unknown coefficients A_1 , B_1 , and B_2 are determined by imposing three boundary conditions. The first two, namely the flux at the water surface ($z = 0$) obtained using Eq. (4) should be equal to F_0 and the concentration at the interface of the two layers ($z = \delta_m$) should be continuous, lead to the following equations:

$$F_0 = F_{m1}(z=0) = (aD)^{1/2}(-A_1 + B_1), \quad (9)$$

$$A_1 \exp(\lambda) + B_1 \exp(-\lambda) - B_2 K_0(\xi_\delta) = 0, \quad (10)$$

where $\xi_\delta = [2ab(\delta_m + (bD/2))]^{1/2}$ and $\lambda = \delta_m(a/D)^{1/2}$.

The third boundary condition can be imposed in a couple of ways, both of which lead to the same answer. First, the total flux at the interface is continuous, i.e.

$$F_{m1}(\delta_m) + a \int_0^{\delta_m} C_1(z) dz = F_{m2}(\delta_m) + a \int_0^{\delta_m} C_2(z) dz, \quad (11)$$

which leads to $F_{m1}(\delta_m) = F_{m2}(\delta_m)$. This, after substituting the flux Eqs. (7) and (8), yields

$$(aD)^{1/2} \{A_1 \exp(\lambda) - B_1 \exp(-\lambda)\} + \frac{B_2}{b} \xi_\delta K_1(\xi_\delta) = 0. \quad (12)$$

Another option as suggested by Fairall et al. (2007) is that as $z \rightarrow \infty$ the mixing term in Eq. (4) becomes 0 so F_0 equals the total absorption of concentration by chemical reaction, i.e.

$$F_0 = a \int_0^{\delta_m} C_1(z) dz + a \int_{\delta_m}^{\infty} C_2(z) dz. \quad (13)$$

This condition leads to exactly the same expression as Eq. (6) when F_0 is substituted from Eq. (9). Solving Eqs. (9), (10), and (12) yields

$$B_1 = \frac{F_0 \exp(\lambda)}{2(aD)^{1/2}} \left[\frac{\psi K_1(\xi_\delta) + K_0(\xi_\delta)}{\psi K_1(\xi_\delta) \cosh(\lambda) + K_0(\xi_\delta) \sinh(\lambda)} \right]. \quad (14)$$

Now A_1 and B_2 can be determined using Eqs. (9) and (10), respectively, after substituting B_1 from Eq. (14). Using Eqs. (5) and (9) we can obtain an expression for the waterside

deposition velocity v_{dw} as the flux (F_0) divided by concentration (C_0) at $z = 0$

$$v_{dw} = (a D)^{1/2} \left[\frac{-A_1 + B_1}{A_1 + B_1} \right], \quad (15)$$

which after substituting for A_1 and B_1 results in

$$\begin{aligned} v_{dw} &= \\ (a D)^{1/2} &\left[\frac{\psi K_1(\xi_\delta) \cosh(\lambda) + K_0(\xi_\delta) \sinh(\lambda)}{\psi K_1(\xi_\delta) \sinh(\lambda) + K_0(\xi_\delta) \cosh(\lambda)} \right], \end{aligned} \quad (16)$$

where $\psi = \xi_\delta / (a b^2 D)^{1/2} = [1 + (\kappa u_{*w} \delta_m / D)]^{1/2}$. Equation (16) is the final expression for v_{dw} and is used to determine r_c as

$$r_c = \frac{1}{\alpha v_{dw}}, \quad (17)$$

where α is the dimensionless solubility of ozone in water (which is the ratio of the aqueous-phase ozone concentration to its gas-phase concentration and is related to Henry's law coefficient). The modified Bessel functions that appear in Eq. (16) were calculated using the algorithms given in Press et al. (1997).

2.1 Asymptotic limits

In the limit $\delta_m \rightarrow 0$, Eq. (16) reduces to

$$v_{dw} = (a D)^{1/2} \left[\frac{K_1(\xi_0)}{K_0(\xi_0)} \right], \quad (18)$$

where $\xi_0 = b(a D)^{1/2}$. This is equivalent to the one-layer model of Fairall et al. (2007), which employs a linearly varying K_t with z and which as mentioned in Sect. 1 overestimates the oceanic deposition velocity measurements of Helmig et al. (2012) by as much as a factor of 2–3 for lower SSTs (Luhar et al., 2017).

In the limit $\delta_m \rightarrow \infty$, the waterside turbulent transfer is neglected and the formulation becomes equivalent to the diffusion-reaction formulation considered by Garland et al. (1980):

$$v_{dw} = (a D)^{1/2}, \quad (19)$$

which underestimates the oceanic deposition velocity measurements for SSTs below 15 °C (Luhar et al., 2017).

2.2 Behaviour of the new scheme and specification of δ_m

The scheme above for determining the oceanic ozone deposition velocity requires specification of the dissolved iodide concentration [I^-] and the second-order rate coefficient (k) for the ozone–iodide reaction used in the calculation of chemical reactivity via $a = k \cdot [I^-]$, the dimensionless solubility of ozone in water (α), the molecular diffusivity of

ozone in water (D), and the waterside friction velocity (u_{*w}). We use

$$[I^-] = 1.46 \times 10^6 \exp \left(\frac{-9134}{T_s} \right) \quad (20)$$

from MacDonald et al. (2014), where $[I^-]$ is in moles per litre (or molar, M). This parameterisation is based on iodide data from cruises in the Atlantic and Pacific oceans covering the latitudes 50° S to 50° N and is a function of SST (T_s (K)), which varies with space and time. Equation (20) yields the highest iodide concentrations in warm tropical waters and the lowest in cool waters at higher latitudes. Chance et al. (2014) examined statistical relationships between iodide and parameters such as SST, nitrate, salinity, chlorophyll *a* and mixed-layer depth and found that SST was the strongest predictor of iodide in surface waters. Ganzeveld et al. (2009) used oceanic surface nitrate as a proxy for $[I^-]$.

The second-order rate coefficient k ($M^{-1} s^{-1}$) based on the data from Magi et al. (1997) is

$$k = \exp \left(\frac{-p}{T_s} + q \right), \quad (21)$$

where $p = 8772.2$ and $q = 51.5$. The ozone solubility is (Morris, 1988)

$$\log_{10}(\alpha) = -0.25 - 0.013(T_s - 273.16). \quad (22)$$

The molecular diffusivity D ($m^2 s^{-1}$) of ozone in water is given as (Johnson and Davis, 1996)

$$D = 1.1 \times 10^{-6} \exp \left(\frac{-1896}{T_s} \right). \quad (23)$$

The waterside friction velocity u_{*w} is calculated as $u_{*w} = (p_a / \rho_w)^{1/2} u_*$, where u_* is the airside friction velocity, ρ_a is the air density, and ρ_w is the water density.

The depth of the reaction–diffusion sublayer (δ_m) needs to be specified. As mentioned earlier, it is of the order of the reaction–diffusion length scale $l_m [= (D/a)^{1/2}]$ so one option is to take $\delta_m = c_0 l_m$ (in that case $\lambda = c_0$), where c_0 is a constant. (With the parameterisations above for $[I^-]$, k , and D , l_m varies between 24.0 and 1.2 µm for the SST range 2–33 °C, and it is 3 µm at 23 °C.) Figure 3 presents the variation in the oceanic component of dry deposition velocity multiplied by the ozone solubility, i.e. αv_{dw} ($= 1/r_c$), calculated from Eq. (16) as a function of SST (Fig. 3a) and reactivity (a) (Fig. 3b) for three c_0 values for a typical value of the waterside friction velocity (u_{*w}) of 0.01 m s⁻¹ (which corresponds to an airside u_* of approximately 0.3 m s⁻¹). The plotted variations show that αv_{dw} increases with SST and with the logarithm of a , both in a very similar manner. As c_0 decreases (hence δ_m decreases) the two-layer model behaviour approaches the behaviour of the one-layer scheme given by Eq. (18) in which turbulent diffusivity is a linear function of depth and chemical reaction is included. Conversely, as c_0 gets larger (hence δ_m gets larger) the extent

of the reaction-diffusion regime in the two-layer scheme gets larger and the model behaviour approaches the limiting behaviour $\alpha v_{dw} = \alpha(aD)^{1/2}$ (Eq. 19) as originally discussed by Garland et al. (1980). In the old two-layer reactivity scheme of Luhar et al. (2017), in some cases αv_{dw} can go below the variation implied by the diffusion-reaction limit (in Eq. 19), which is not realistic and does not occur with the new scheme.

In Fig. 3b, as a decreases δ_m increases (since $\delta_m = c_0(D/a)^{1/2}$), and the model approaches the diffusion-reaction limit Eq. (19) of Garland et al. (1980). As a increases δ_m decreases, and the model approaches the one-layer solution Eq. (18). Figure 3a shows the same behaviour but in terms of SST.

It is found that the use of $\delta_m = c_0 l_m$ together with the parameterisations in Eqs. (20)–(23) does not fully describe the variation in the measured deposition velocities with SST (presented later) regardless of the value of c_0 . For example, with $c_0 = 0.7$ there is an underestimation by the model of the measured deposition velocities for SSTs less than 18 °C and an overestimation for higher SSTs. For $c_0 < 0.7$ the overestimation gets worse. For $c_0 > 0.7$ the underestimation gets worse and the αv_{dw} variation approaches the diffusion-reaction behaviour.

Another method for specifying δ_m is to assume that it is constant. Figure 3 shows the variation in αv_{dw} calculated from Eq. (16) as a function of SST (Fig. 3c) and a (Fig. 3d) for several fixed values of δ_m between 0.5 and 10 µm. These variations look different compared to those in Fig. 3a and b but like the latter they all fall within the two limits. As δ_m decreases the αv_{dw} variation approaches the one-layer solution Eq. (18) and as δ_m increases this variation approaches the diffusion-reaction limit Eq. (19).

There are further considerations to the parameterisations. There is uncertainty in the parameterisations in Eqs. (20)–(23), particularly in the second-order rate coefficient k for which there is a paucity of data. The expression, Eq. (21), is based on the data from Magi et al. (1997), which are plotted in Fig. 4 with the associated uncertainty. Also plotted are the single data points from Garland et al. (1980), Hu et al. (1995), and Liu et al. (2001). Clearly there is a large scatter in the data. Five options are considered (option 6 is discussed later) with regards to parameterising k via an exponential fit of the form as Eq. (21).

1. Only consider the data of Magi et al. (1997) (so the fit is the same as Eq. 21 with the stated p and q values).
2. Consider all the data (which gives $p = 2349.2$ and $q = 29.2$).
3. Consider all the data except the data point of Hu et al. (1995), which is treated as an outlier (which gives $p = 5632.9$ and $q = 40.3$).
4. Assume a constant $\delta_m = 3 \mu\text{m}$ with k given by Eq. (21) using only the data of Magi et al. (1997).

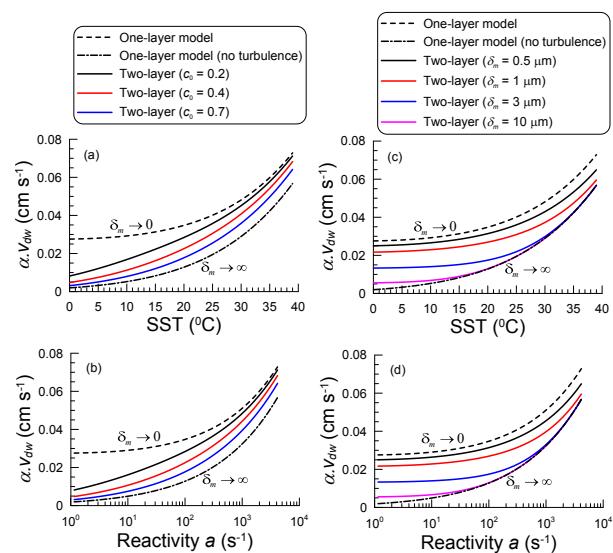

Figure 3. Variation in the waterside component of ozone dry deposition velocity multiplied by ozone solubility, $\alpha v_{dw} (= 1/r_c)$, as a function of sea surface temperature (SST, °C) (**a, c**) and reactivity a (s^{-1}) (**b, d**). Curves determined using the two-layer deposition scheme (Eq. 16) for several c_0 values used in $\delta_m = c_0 l_m$ (**a, b**) and several δ_m values (**c, d**). The variations obtained using the one-layer deposition scheme with (Eq. 18) and without (Eq. 19) waterside turbulent transfer (i.e. reaction–diffusion only) are also shown. The waterside friction velocity (u_{*w}) used was 0.01 m s^{-1} .

5. Assume a constant $k = 2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ as in MacDonald et al. (2014).

In Fig. 3a and b, all five curves fall within the two asymptotic limits (equivalent to $c_0 \rightarrow 0$ and $c_0 \rightarrow \infty$). The $c_0 = 0.4$ curve roughly lies in the middle of the two asymptotic limits and this value of c_0 was used in calculating $\delta_m = c_0 l_m$ in all the options above, except option 4, which does not need a specification of c_0 (but there will obviously be an implied variation of c_0 through the relation $c_0 = \delta_m/l_m$). Figure 5 shows the variation of αv_{dw} calculated from Eq. (16) as a function of SST for the five options above. All five options provide qualitatively similar variations of αv_{dw} with SST, but when compared with the cruise measurements of oceanic deposition velocities (v_d) discussed later (which themselves have substantial scatter) in Sect. 4.1, options 3 and 4 provide better agreement overall with the measurements compared to the other options (noting that v_d is dominated by the term αv_{dw} for water). Option 3 tends to underestimate the observed deposition velocities by roughly 15 % for SSTs less than around 12 °C whereas option 4 tends to overestimate them by about the same degree. For higher SSTs, both options perform similarly, with option 4 being very slightly better for SSTs greater than 20 °C, within the scatter of the measurements.

We also include in Fig. 5 an additional curve as option 6, which is the same as option 4 but using the Chance et

al. (2014) parameterisation for iodide concentration (in molar)

$$[I^-] = [0.225(T_s - 273.16)^2 + 19] \times 10^{-9}. \quad (24)$$

Compared to option 4, option 6 results in larger αv_{dw} values and the relative difference between the two increases with SST; for example, for SSTs 5, 20, and 30 °C, the option 6 value is larger by 13, 29, and 33 %, respectively. Consequently, option 6 would overestimate the observed ozone deposition velocity data presented later in Fig. 7, almost passing along the upper limits of the observed fluctuations in v_d . However, if option 6 is used along with the second-order rate constant (k) without considering the data point of Hu et al. (1995) as in option 3 (which gives lower k values), then the values of deposition velocity obtained are comparable to those obtained using option 4 for the same δ_m . This is because a larger iodide concentration is compensated for by a lower k in the expression for reactivity $a (= k \cdot [I^-])$, which is what goes directly into the deposition velocity calculation.

Clearly there is significant uncertainty in the representation of iodide concentration $[I^-]$ and k , and certain choices of the input parameterisations can describe deposition velocity observations better than others. Overall, the calculation of ozone deposition velocity using the model presented here is a rather poorly constrained problem in which multiple choices of input parameters can give the same or very similar calculated deposition velocity. The best constrained at this stage is the comparison of the calculated deposition velocity with that observed.

In the calculations below, unless otherwise stated, we have used option 4 for δ_m and k . In Sect. 4.1, this option 4 is used for calculating v_d in ACCESS-UKCA and comparing the modelled v_d values with measurements and with other deposition schemes or configurations. In Sect. 5.3 we estimate a measure of uncertainty in our deposition flux estimates taking into account the scatter in the ocean deposition velocity data used.

2.3 Impact of ozone reaction with dissolved organic carbon (DOC)

Some studies have considered the impact on dry deposition of ozone reaction with dissolved compounds other than iodide. In general, the inclusion of additional reactions in the deposition mechanism enhances the ozone loss to the ocean and thus increases deposition velocities. Chang et al. (2004) included reactions of ozone with iodide, dimethyl sulfide (DMS), ethene, and propene and showed that the reaction with iodide was by far the fastest (hence most important) in most cases. In their global modelling, Ganzeveld et al. (2009) included ozone reaction with chlorophyll a as a first-order approximation to examine the possible role of dissolved organic matter (DOM) and found that this reaction significantly increased dry deposition velocities at coastal sites (with mixed results compared to observations) and yielded

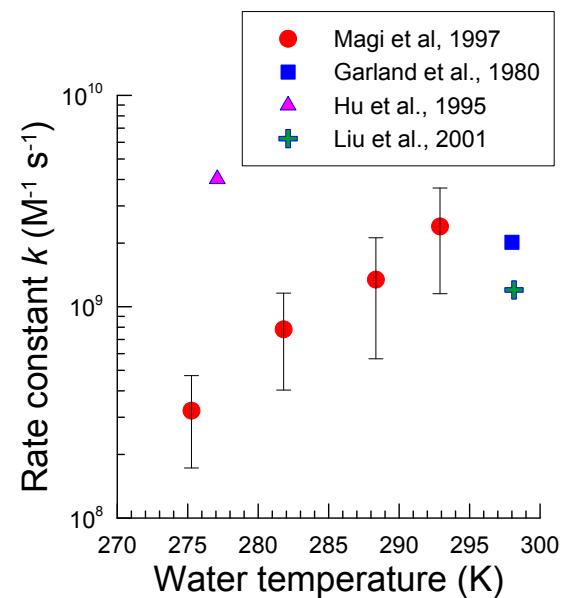

Figure 4. The second-order rate coefficient (k) for the ozone–iodide reaction as a function of water temperature. Data from various studies are shown.

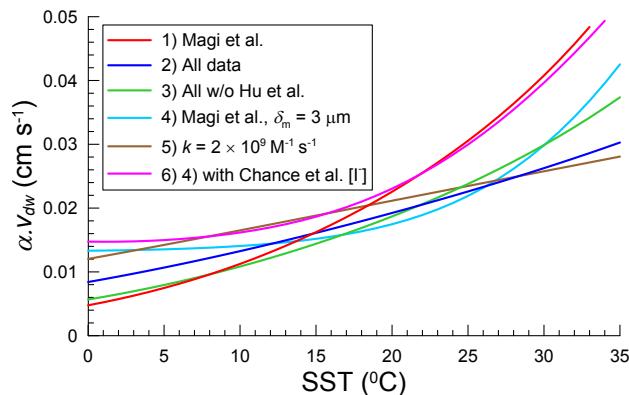

Figure 5. Variation in the oceanic component of ozone dry deposition velocity multiplied by ozone solubility, αv_{dw} ($= 1/r_c$), as a function of sea surface temperature (SST, °C). Curves determined using the two-layer deposition scheme (Eq. 16) for various options for parameterising the second-order rate coefficient (k) (see text). The waterside friction velocity (u_{*w}) used was 0.01 m s^{-1} .

only small changes to deposition velocity for open-ocean sites. Sarwar et al. (2016) included ozone reactions with iodide, dissolved organic carbon (DOC) (a measure of DOM), DMS, and bromide in their ozone modelling for summer months in the Northern Hemisphere and found that the impact of DOC on the simulated deposition velocity was comparable to that of iodide, with the other reactions contributing much less. Coleman et al. (2010) showed that in addition to iodide the inclusion of DOC in their empirical scheme described daytime deposition observations better in coastal wa-

ters of the North Atlantic. We are not aware of any previous studies that have compared modelled deposition velocities involving the impact of the aqueous O₃-DOC reaction with the open-ocean observations of Helmig et al. (2012) and their dependence on SST. It is instructive to carry out a simple sensitivity analysis involving ozone reaction with DOC. (Our new two-layer parameterisation is applicable to any other chemical compounds that are taken up by the oceanic mixing layer as long as the reaction-diffusion length scale is smaller than the depth of the viscous sublayer.)

For open-ocean surface waters, Hansell et al. (2009) report DOC concentration values of 70–80 µM in tropical and subtropical regions (40° N–40° S), ~40–50 µM in subpolar seas and in the circumpolar Southern Ocean (> 50° S), and about 70 µM in the Arctic Ocean (> 70° N). Based on Hansell et al. (2009), Sarwar et al. (2016) used a mean DOC concentration of 67 µM over the Northern Hemisphere. A recent analysis by Massicotte et al. (2017) gives an average DOC value of 52 µM for oceans.

There are no definitive, directly measured values available for the second-order rate coefficient (k) for the DOC–O₃ reaction. Coleman et al. (2010) empirically derived $k = 3.44 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ based on data fitting, whereas Sarwar et al. (2016) used $k = 4.0 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$, noting that this value together with their selected DOC concentration yields a first-order rate constant of ~268 s⁻¹ that lies between the two values 100 s⁻¹ (open ocean) and 500 s⁻¹ (coastal waters) used by Carpenter et al. (2013) based on the modelling by Ganzeveld et al. (2009). This reactivity value lies within the range of reactivity plotted in Fig. 3.

Clearly there is considerable uncertainty in k for the DOC–O₃ reaction and in the DOC concentration and its variability. Dependencies of k , such as how it may vary with SST, are not known. For our purposes, we use a mean $k = 3.7 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ (which is in the middle of the two values noted above) and a DOC concentration of 52 µM (Massicotte et al., 2017) in our two-layer scheme, together with an integrated chemical loss rate $a = \sum k_i C_i$, where the summation is over the iodide and DOC reactions ($i = 1, 2$).

Figure 6 shows the variation of αv_{dw} as a function of SST determined using our two-layer deposition scheme incorporating the ozone reaction with (1) only iodide (this curve is the same as option 4 in Fig. 5 with $\delta_m = 3 \mu\text{m}$), (2) only DOC, and (3) the two reactions together for three values of δ_m . Compared to the iodide-only curve, the inclusion of DOC leads to a progressive increase in αv_{dw} as SST decreases for all values of δ_m . As δ_m increases αv_{dw} decreases, but increasing δ_m beyond 6 µm has virtually no impact on αv_{dw} (not shown). When only DOC is considered, αv_{dw} decreases with SST. Given that the αv_{dw} term dominates in the determination of v_d , the behaviour of the former represents that of the latter. In Sect. 4.1 below, we show that the addition of DOC in the deposition scheme deteriorates the model–data agreement for deposition velocity. (We note that for coastal waters, not explicitly investigated here (see Sect. 4.2), the case

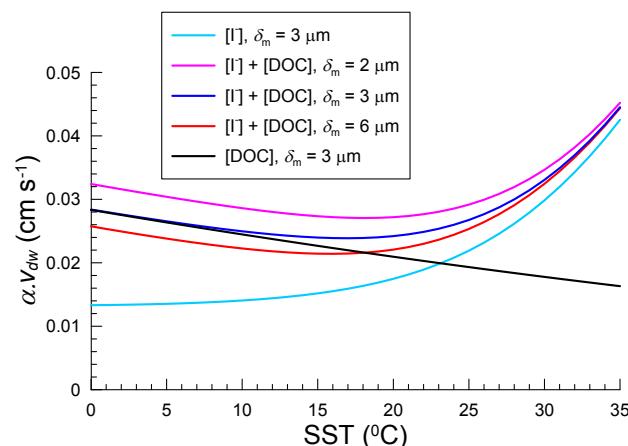

Figure 6. Variation in the oceanic component of ozone dry deposition velocity multiplied by ozone solubility, αv_{dw} ($= 1/r_c$), as a function of sea surface temperature. Curves determined using the present two-layer deposition scheme incorporating the ozone reaction with iodide [I^-], dissolved organic carbon [DOC], and the two reactions together ($[I^-] + [\text{DOC}]$). The waterside friction velocity (u_{*w}) used was 0.01 m s^{-1} .

may be different.) Lowering the DOC concentration in the model to the lowest levels ($\sim 40 \mu\text{M}$) reported by Hansell et al. (2009) does not improve the agreement either. A k value for the DOC–O₃ reaction that decreases with SST (like that for the iodide–O₃ reaction) could explain the deposition velocity data better, but any such k observations are lacking at present.

3 ACCESS-UKCA chemistry–climate modelling system

The two-layer dry deposition scheme developed above was implemented in the UKCA (<http://www.ukca.ac.uk>) global atmospheric composition model (Morgenstern et al., 2009; Abraham et al., 2012; O'Connor, 2014), which is a component in ACCESS (Bi et al., 2013; Woodhouse et al., 2015). The physical atmosphere component of ACCESS-UKCA is the same as the UK Met Office's Unified Model (UM) (at UM vn8.4; Walters et al., 2014). In our simulations, ACCESS-UKCA is essentially the same as UM-UKCA since the ACCESS-specific ocean and land-surface components are not invoked. This is because we run the model in atmosphere-only mode with prescribed SSTs, and the UM's original land-surface scheme (JULES) is used. The particular UKCA configuration used here (at UM vn8.4) is the so-called Chemistry of the Stratosphere and Troposphere (CheST). ACCESS-UKCA uses the monthly mean SST and sea ice fields prescribed from the Atmospheric Model Intercomparison project (AMIP). The atmospheric model has a horizontal resolution of 1.875° in longitude and 1.25° in latitude and 85 levels extending from the surface to approxi-

mately 85 km (the N96L85 configuration). The model was nudged to the ERA-Interim meteorological reanalyses (Dee et al., 2011), given on pressure levels, for the horizontal wind and potential temperature in the free troposphere (Uhe and Thatcher, 2015). Other model setup details are as in Woodhouse et al. (2015).

There are nine surface types in the model, namely broadleaf trees, needleleaf trees, C3 grass, C4 grass, shrub, urban, water, bare soil, and land ice. For every surface grid box the three resistances r_a , r_b , and r_c are calculated for each surface type and a corresponding v_d is then computed. For the water surface, standard expressions for r_a and r_b are used by ACCESS-UKCA in Eq. (2) (see Abraham et al., 2012; Luhar et al., 2017) and r_c is computed using Eq. (17) together with Eq. (16). Currently there is only one water surface type in the model, so the same deposition scheme is used for both seawater and freshwater. The SSTs prescribed in the model for every grid box vary with time and are used in the input parameterisations in Eqs. (20)–(24). A grid-box mean deposition velocity and the corresponding loss rate are calculated using the individual deposition velocities weighted by the fractions of the surface types present in the grid box and this loss rate is applied to the lowest model grid box in the species mass conservation equation. For a coastal grid box that also includes fractions of non-water surfaces, we use the two-layer deposition scheme when the fraction of the water surface in the grid box is greater than 60 %. In all other cases the default Wesely (1989) scheme for v_d is used, involving the use of $r_c = 2200 \text{ s m}^{-1}$ for the water surface.

The ozone dry deposition velocity in the model is solely a function of parameters of the physical component of the model (e.g. SST, flow properties and turbulent mixing, and surface characteristics) and prescribed input parameters (e.g. reactivity, ozone molecular diffusivity, and solubility in water) and is unrelated to the tropospheric ozone chemistry within the model.

Ozone dry deposition budgets can be better constrained by using tropospheric ozone reanalyses which are taken as a more reliable source of ozone data than those obtained by models alone. In Sect. 5, we follow this approach, in which the gridded 3-hourly MACC global reanalyses of near-surface ozone for the period 2003–2012 (Inness et al., 2013; <http://apps.ecmwf.int/datasets/data/macc-reanalysis>) are multiplied by the gridded 3-hourly dry deposition velocities obtained from ACCESS-UKCA to calculate ozone deposition flux (and hence the annual deposition loss). Because we use the MACC ozone, the derived deposition fluxes do not depend on ACCESS-UKCA's ozone chemistry.

4 Ozone dry deposition velocity to the ocean

4.1 Comparison with observations

We use the ozone dry deposition velocity measurements of Helmig et al. (2012) taken over the open ocean from a ship-based system during 2006–2008 which spanned 45° N to 50° S. Additional details of these data are given by Bariteau et al. (2010). Surface-based ozone flux stations employing the eddy-covariance technique enable a direct measurement of ozone dry deposition velocity. The data of Helmig et al. (2012) are the only such measurements available to date over the open ocean. These authors also summarise deposition velocity measurements reported in earlier studies, which are very sparse and none of these studies involved a surface-based eddy-covariance technique over the open ocean (there were a few data points for coastal locations and from aircraft-based systems using such a technique). Given the substantially larger sample size for a range of SSTs, and presumably the use of improved instrumentation and analysis techniques in the cruise measurements of Helmig et al. (2012) compared to those reported by earlier studies, we only consider the cruise data.

The ship-based experiments were conducted on five cruises, namely

1. TexAQS06 (7 July–12 September 2006),
2. STRATUS06 (9–27 October 2006),
3. GOMECC07 (11 July–4 August 2007),
4. GasEx08 (29 February–11 April 2008), and
5. AMMA08 cruises (27 April–18 May 2008).

The respective areas covered were

1. the north-western Gulf of Mexico,
2. the persistent stratus cloud region off Chile in the eastern Pacific Ocean,
3. the Gulf of Mexico and the US east coast,
4. the Southern Ocean, and
5. the southern and northern Atlantic Ocean.

Helmig et al. (2012) present bin-averaged deposition velocity data as a function of SST and wind speed for each of the five cruises. As in Luhar et al. (2017), the v_d versus SST cruise data used for comparison with the model are those with the wind speed dependence retained (Ludovic Bariteau, personal communication, 2016) and not the data originally reported by Helmig et al. (2012) in which the wind-speed dependence was removed. While this approach is logically correct, there is not a large difference between the data with and without the wind-speed dependence.

ACCESS-UKCA output including dry deposition parameters is available at 3 h time intervals and also as monthly averages over the period 2003–2012. Because the data are averaged with respect to SST or wind-speed bins for each cruise and as a result there is no explicit dependence present as to the exact timings and locations of the data along a cruise track, we used the same methodology as that in Luhar et al. (2017) for comparing the v_d data with ACCESS-UKCA. In summary, as the months corresponding to the cruise experiments are known, the model monthly averages matching the experimental months were selected. For a given month, the monthly averaged model output was extracted at a series of grid-box locations (fully covered by water) with almost uniform spacing along the tracks of the experimental cruises, and the modelled values at these locations were used for comparison with the measurements. Clearly this is an approximate matching of the deposition velocity data and the modelled values in terms of time and location.

Figure 7 shows the observed ozone dry deposition velocity (v_d) as a function of SST from the five field experiments and the corresponding values obtained from the ACCESS-UKCA model using the new two-layer scheme (Eq. 16). The SST range for the measurements is 2–33 °C with the lowest values being for GasEx08 and the highest for TexAQS06 and GOMECC07. Despite the large fluctuations within the field data, an increasing trend of v_d with SST is clearly identifiable. Helmig et al. (2012) compiled a historical record of ozone deposition velocities over water (their Fig. 4) starting from the year 1969 which lie within the range of 0.01–0.15 cm s⁻¹. The range of the cruise measurements in Fig. 7, which are the only direct, open-ocean flux measurements, is 0.005–0.06 cm s⁻¹, which is on the lower end of the range of the historical data. As stated by Helmig et al. (2012), the earlier experiments, lacking ocean-deployable measurement techniques, are biased toward coastal waters, which may carry higher concentrations of ozone reactants that lead to increased deposition velocities. Another reason for the difference could be the use of improved experimental techniques in the cruise measurements.

Figure 8 presents a scatter plot of the observed deposition velocities averaged over the data from each of the five cruise experiments versus the corresponding values obtained from the model (with the error bars representing 1 standard deviation variation). The correlation between the modelled v_d and data is good ($r^2 = 0.86$). Although Figs. 7 and 8 show that the model is able to describe the SST dependence and the absolute magnitude of the field measurements, it is clear that there are some significant fluctuations in the measurements, particularly for SSTs within the range of 8–24 °C, that are not present as prominently in the modelled values. There could be a number of possible reasons for this:

1. the monthly averaged modelled deposition values used and the approximate method followed for matching the data and for time and location;

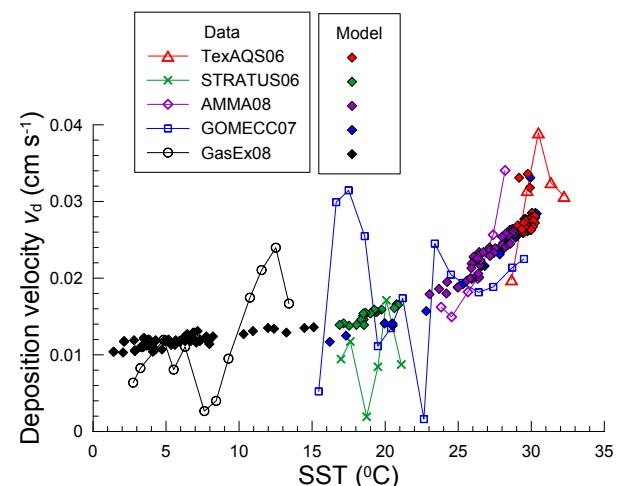

Figure 7. Ozone dry deposition velocity (v_d) as a function of sea surface temperature (SST) from five field experiments (Helmig et al., 2012; Ludovic Bariteau, personal communication, 2016) and the corresponding values obtained from the ACCESS-UKCA model using the new two-layer scheme (Eq. 16) for ozone deposition to the ocean.

2. the dissolved iodide concentrations are not directly available and the parameterisation used here only depends on SST; and
3. the observed SSTs used in our atmosphere-only model set-up are monthly averaged – a model set-up with a coupled ocean model that interacts with the atmosphere at sub-diurnal intervals would provide a better SST variability, which would in turn influence the variability in the iodide concentration and thus impact the modelled deposition velocity.

Needless to say, additional measurements of ozone dry deposition velocity and governing parameters (e.g. iodide concentrations, SST, DOC, nitrate) with greater temporal and spatial coverage would help to further assess the scheme.

The model results in Fig. 7 are very similar to those obtained by Luhar et al. (2017) using their two-layer reactivity scheme (their Fig. 6), but unlike the old two-layer scheme the new two-layer scheme performs well for the right reasons – as discussed earlier the old scheme artificially limits chemical reactivity to the reaction-diffusion sublayer in order to compensate for the overestimation of the impact of waterside turbulence due to a turbulent diffusivity parameterisation that is not appropriate very close to the water surface.

The performance with ranking of the various ozone dry deposition velocity schemes or configurations (within ACCESS-UKCA) for seawater discussed above compared to the v_d observations plotted in Fig. 7 is summarised in Table 1 in terms of some commonly used statistical measures, which were calculated using the bin-averaged modelled and observed v_d values within SST bins of 5 °C lying within the

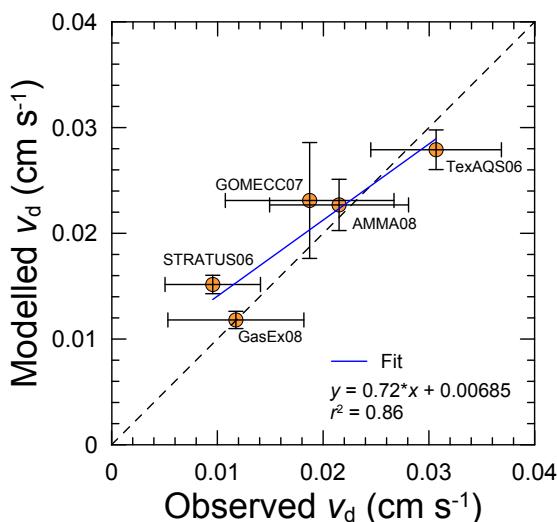

Figure 8. Scatter plot of the ozone dry deposition velocities (v_d) obtained from the five cruise experiments versus the corresponding values obtained from the ACCESS-UKCA model using the new two-layer scheme (Eq. 16). Each point corresponds to the average over all values from one experiment. The error bars represent 1 standard deviation variation. Horizontal error bars are for the observed values and the vertical ones are for the modelled values.

range of 1–35 °C (sample size = 7). The measures used are the ratio of modelled mean to observed mean (\bar{M}/\bar{O}), fractional bias (FB, varies between +2 (underestimation) and -2 (overestimation)), normalised mean square error (NMSE), and index of agreement (IOA, varies between 0 and 1). For a perfect agreement, the values of these parameters should be 1, 0, 0, and 1, respectively. Unlike the correlation coefficient (r), IOA is sensitive to differences between the observed and model means as well as to certain changes in proportionality and is thus preferred for model evaluation (Willmott, 1981).

In the schemes in Table 1, unless stated otherwise, the second-order rate coefficient is given by Eq. (21) using only the data of Magi et al. (1997), and the MacDonald et al. (2014) iodide parameterisation (Eq. 20) is used. In Table 1, the new two-layer scheme with $\delta_m = 3 \mu\text{m}$ (as used in the model–data comparison plots above and in all the calculations below) performs the best, followed by the same scheme with the Chance et al. (2014) iodide parameterisation (Eq. 24) which overestimates the v_d data. The next two schemes in the ranking are the one-layer scheme of Fairall et al. (2007) without waterside turbulence, Eq. (19), which is equivalent to the diffusion-reaction formulation considered by Garland et al. (1980) and which underestimates the deposition velocity data, and the two-layer scheme that also includes the DOC– O_3 reaction which overestimates the data. The largest overestimation of the v_d data is through the use of constant $r_c = 2200 \text{ s m}^{-1}$ and to a slightly lesser extent by the one-layer scheme of Fairall et al. (2007), Eq. (18). The model–data comparison above suggests that the two-layer

scheme with the soundly based iodide mechanism is able to describe the deposition velocity measurements for the open ocean well and we use this set-up hereafter.

4.2 Global distribution

Figure 9 shows the distribution of ozone deposition velocity (cm s^{-1}) to the ocean (not including sea ice) obtained using the new two-layer scheme within ACCESS-UKCA for the year 2005. The year 2005 is chosen to illustrate the spatial variability because, as will be discussed later, the MACC ozone reanalysis has the least bias for this year (however, we note that the interannual variability in the modelled deposition velocity fields is small). The largest open-ocean deposition velocities occur in the tropics where both the observed (Chance et al., 2014; MacDonald et al., 2014) and parameterised iodide concentrations, which are proportional to SST, are the largest, and the magnitude of deposition velocities decreases with increasing latitude.

Figure 9 also shows the modelled deposition velocities over the coastal grid boxes that contain some fractions of both water and land surfaces. For such grid boxes, the modelled deposition velocities are typically $0.1\text{--}0.2 \text{ cm s}^{-1}$, which is much greater than those for grid boxes fully covered by water. This is because terrestrial surfaces have higher deposition velocities than water and also partly because of the use of the larger deposition rate through the use of $r_c = 2200 \text{ s m}^{-1}$ for the water surface tile when its fraction is less than 60 % within a grid cell. There is some evidence that the measured ozone deposition velocities over coastal waters are larger than those over open oceans (e.g. Coleman et al., 2010; Bariteau et al., 2010), which could be due to factors such as stronger chemical reactivity and turbulence, and advection from land if the distance between the monitor and coastline (i.e. fetch) is limited. Our approach for treating coastal water grid boxes is qualitatively consistent with ozone deposition velocities over coastal waters being larger than over the open sea, but here we have not examined or included any particular mechanistic processes that are relevant for coastal waters. High-resolution, regional, or small-scale modelling could be useful in exploring such processes and their spatial and temporal scale and variability.

5 Dry deposition budgets using the MACC ozone reanalysis

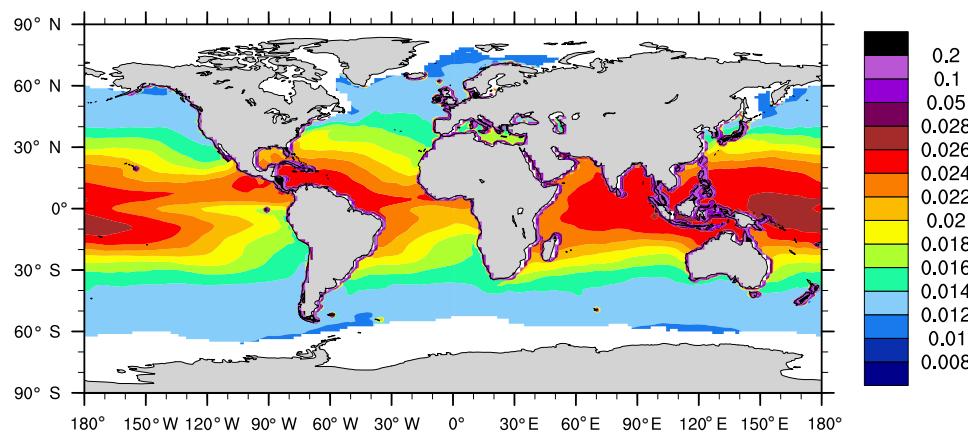

Ozone deposition fluxes are calculated from ozone concentrations in near-surface air and associated ozone deposition velocities. In this study, the MACC near-surface ozone data are used.

The global model used for deriving the MACC reanalysis consists of the European Centre for Medium-Range Weather Forecasts' (ECMWF) Integrated Forecast System (IFS) coupled to the MOZART (Model for OZone And Related chem-

Table 1. Performance statistics of various ozone dry deposition velocity schemes for seawater compared to the observations plotted in Fig. 7*.

Scheme	$\overline{M}/\overline{O}$	FB	NMSE	IOA	Ranking
Present two-layer scheme	0.99	0.01	0.06	0.92	1
Present two-layer scheme with the Chance et al. (2014) [I^-]	1.20	-0.19	0.09	0.88	2

* Observed mean (\overline{O}), modelled mean (\overline{M}), fractional bias (FB) = $2(\overline{O} - \overline{M}) / (\overline{O} + \overline{M})$, normalised mean square error (NMSE) = $(\overline{M} - \overline{O})^2 / (\overline{M} \cdot \overline{O})$, and index of agreement (IOA) = $1 - [(M - O)^2 / (|M - \overline{O}| + |O - \overline{O}|)^2]$.

**Figure 9.** Annual mean ozone dry deposition velocity (v_d , cm s^{-1}) to the ocean for the year 2005 obtained from the ACCESS-UKCA model incorporating the oceanic dry deposition scheme proposed in this paper. Deposition velocities over the coastal grid boxes are also shown.

ical Tracers) chemistry transport model (Kinnison et al., 2007). The modelling system makes use of four-dimensional variational data assimilation to combine satellite retrievals of carbon monoxide, ozone, and nitrogen oxides as well as the standard meteorological observations with the numerical model in order to produce a reanalysis of atmospheric composition. For ozone, profile, total column, and partial column data are assimilated.

The MACC reanalysis has been evaluated against multiple observational networks of ground-based measurements, ozonesondes, and aircraft and satellite data (Inness et al., 2013; Gaudel et al., 2015; Giordano et al., 2015; Kastrigou et al., 2015; http://macc.copernicus-atmosphere.eu/documents/maccii/deliverables/val/MACCII_VAL_DEL_D_83.6_Report04_20140729.pdf). These evaluation studies suggest that the assimilation of composition data generally improves the modelled tropospheric ozone fields, noting that there are some exceptions which highlight the fact that assimilation does not always yield a close match with observations and that the results depend on several factors such as the quality and quantity of data being

assimilated, the type of modelling system, and the data assimilation methodology used.

The MACC composition reanalysis is given at 60 hybrid sigma-pressure levels, from near the surface (1012 hPa, 10 m geometric altitude) to 0.1 hPa (~ 65.6 km) covering both the troposphere and the stratosphere. The MACC ozone data at the 10 m level (L60) were extracted at a horizontal resolution of $1.125^\circ \times 1.125^\circ$ at 3 h time intervals and were regridded to the ACCESS-UKCA N96 horizontal grid using bilinear interpolation. These data were then multiplied by the time-matched 3 h deposition velocity fields obtained from ACCESS-UKCA (with the new two-layer ocean deposition scheme) to calculate the deposition flux and total deposition loss. The use of a 3-hourly temporal resolution, which is the finest available for the MACC reanalysis, ensures that any (e.g. diurnal) covariance of near-surface ozone and deposition velocity is accounted for in calculating total dry deposition. We find that this covariance based on the 3 h fields for the ocean is small and leads to a small increase of 1.4 % in the annual deposition flux to the ocean compared to when monthly averaged fields of deposition velocity and ozone concentration are used. Conversely, this increase is about

28 % over land surfaces, demonstrating a considerable degree of covariance. The likely reason for the small covariance over the ocean surface is that the near-surface ozone is influenced more by vertical turbulent exchange than by dry deposition due to the relatively small values of v_d over such surfaces. In contrast, deposition velocities over land surfaces are large and they influence the near-surface ozone to a greater degree than turbulent vertical air exchange, particularly during stable conditions. The MACC data for all 10 years were used, which is useful for examining interannual variability in deposition.

5.1 Global distribution of surface ozone and dry deposition flux

As an example, Fig. 10a shows the mean surface ozone mixing ratio (ppbv) based on the MACC reanalysis for 2005. It is apparent that relatively high values occur in the Northern Hemisphere, particularly in the mid-latitudes, which can be attributed to the larger precursor emissions in these areas. The mixing ratios over the ocean are generally greater than those over the land, which can be partly attributed to the smaller dry deposition velocities to the ocean and hence lower deposition. There are ozone minima around the Equator, especially over the Pacific Ocean.

The annual oceanic ozone dry deposition flux obtained using the MACC ozone reanalysis coupled with the deposition velocities from ACCESS-UKCA averaged over 2005 presented in Fig. 10b indicate that the largest flux values between 0.014 and 0.02 $\mu\text{g m}^{-2} \text{s}^{-1}$ are observed within latitudes 10–40° N. The flux in the Southern Hemisphere is lower than that in the Northern Hemisphere and decreases with latitude.

5.2 Dry deposition budgets

Figure 11 presents the annual ozone dry deposition obtained using the MACC reanalysis as a function of year. The oceanic deposition (Fig. 11a) lies between 86.5 and 108.3 Tg (as O₃) per year with the average being $93.9 \pm 7.5 \text{ Tg yr}^{-1}$, where the error bounds correspond to 1 standard deviation and are solely due to interannual variation. (In our calculations, the oceanic component excludes sea ice and coastal grid boxes and on average covers 62.4 % of the Earth's surface.) The largest deposition occurs for 2005–2007. Oceanic deposition in the Northern Hemisphere ($49.0 \pm 3.4 \text{ Tg yr}^{-1}$) is somewhat larger than that in the Southern Hemisphere ($44.9 \pm 4.5 \text{ Tg yr}^{-1}$) due to the higher O₃ concentrations and slightly larger oceanic deposition velocities in the former, although the Earth's area covered by the ocean is larger by approximately 30 % in the Southern Hemisphere. The main reason why the dry deposition velocities to the ocean in the Northern Hemisphere are larger (e.g. 0.020 vs. 0.017 m s^{-1} on average for the year 2005) is that the SSTs for the Northern Hemisphere are warmer than those for the Southern

Hemisphere (e.g. 295.3 K vs. 291.2 K on average for the same year). In our formulation, deposition velocity to the ocean is dominated by the surface-resistance term (r_c) which in turn depends on SST. Overall the higher the SST the higher the oceanic deposition velocity. There is a hint in Fig. 11a that the pattern of interannual variability in the global oceanic deposition follows that for the Southern Hemisphere more closely.

The variation in the global total deposition obtained using the MACC reanalysis in Fig. 11b is in the range of 636.9–766.3 Tg yr^{-1} and the mean value is $689.9 \pm 47.0 \text{ Tg yr}^{-1}$ with the largest deposition amounts for 2005–2007. The total deposition to the Northern Hemisphere ($497.5 \pm 36.9 \text{ Tg yr}^{-1}$) is 72 % of the total deposition and is 2.5 times larger than that to the Southern Hemisphere ($192.4 \pm 11.4 \text{ Tg yr}^{-1}$) because in the former the O₃ concentrations are larger coupled with the larger coverage of the Earth's area by land for which deposition velocities are larger than for water. On average, deposition to the ocean is approximately 14 % of the total deposition. The pattern of interannual variability in the global deposition is dominated by that for the Northern Hemisphere. This variability is driven by MACC ozone concentration changes rather than changes in deposition velocity.

The MACC reanalysis is not free from bias as demonstrated in a number of studies (e.g. Inness et al., 2013; Gaudel et al., 2015; Giordano et al., 2015; Katragkou et al., 2015). With regards to global bias in surface ozone, Fig. 12 presents the annual averaged normalised median bias (%) of the MACC ozone mixing ratios relative to the Global Atmosphere Watch (GAW) surface observations (http://www.wmo.int/pages/prog/arep/gaw/gaw_home_en.html) for the years 2003–2012. We have derived this bias using the seasonal bias data taken from Benedictow et al. (2014) (http://macc.copernicus-atmosphere.eu/documents/maccii/deliverables/val/MACCII_VAL_DEL_D_83.6_REReport04_20140729.pdf). Figure 12 shows that except for the first year the bias has remained within $\pm 10 \%$ and has been negative since 2008. The bias is the smallest for the year 2005. The total deposition for that year is 729.8 Tg yr^{-1} , of which 527.1 Tg yr^{-1} is to the Northern Hemisphere and 202.7 Tg yr^{-1} is to the Southern Hemisphere. The total oceanic deposition for that year is 99.9 Tg yr^{-1} , of which 52.0 Tg yr^{-1} is to the Northern Hemisphere and 47.9 Tg yr^{-1} is to the Southern Hemisphere. Thus the total deposition to non-water surfaces is 629.9 Tg yr^{-1} .

Interestingly, the shape of the interannual variation in total deposition in Fig. 11b (and also the interannual variation in total oceanic deposition in Fig. 11a) is similar to that of the bias in Fig. 12, suggesting that the interannual variability in dry deposition may at least partly be due to the interannual variability in bias in the MACC ozone. Figure 13 is a scatter plot of the annual averaged bias (%) in the MACC ozone versus the total global deposition and total oceanic deposition determined based on the MACC data for the years

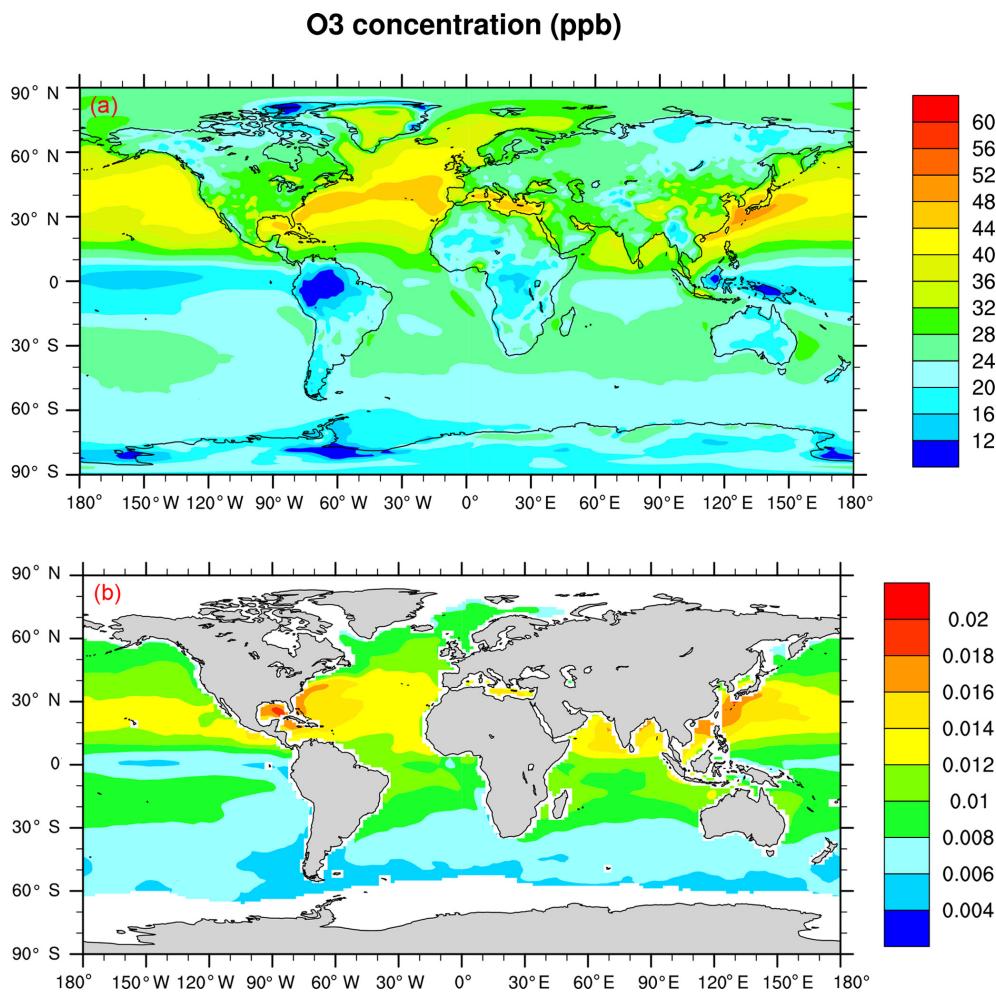

Figure 10. (a) Mean surface ozone mixing ratio (ppbv) and (b) mean oceanic ozone dry deposition flux ($\mu\text{g m}^{-2} \text{s}^{-1}$) for 2005 obtained from the MACC reanalysis.

2003–2012. The annual bias and deposition appear well correlated, with a liner correlation $r^2 = 0.83$ for the total deposition and $r^2 = 0.65$ for the oceanic deposition. Based on the linear fits, the annual ozone deposition value corresponding to zero bias is 717.6 Tg yr^{-1} for the globe and 97.8 Tg yr^{-1} for the ocean.

The bias correction above does not provide information on annual variability without bias. A simple (but rather crude) way to correct the MACC-based deposition (d_{p0}) for each year for the bias (b_s) is to calculate a new annual deposition $d_p = d_{p0}(1 - b_s/100)$ and then calculate the average over the 10 years and the corresponding standard deviation. By assuming that the observed global bias is uniform over the land, ocean, and hemispheric components, averages and standard deviations for these components can also be derived. The bias-corrected deposition values are plotted in Fig. 11. Based on these, the average oceanic deposition is $98.4 \pm 4.5 \text{ Tg yr}^{-1}$ and the average total global deposition is $722.8 \pm 20.9 \text{ Tg yr}^{-1}$. The total deposition to non-water sur-

faces is $624.4 \pm 17.4 \text{ Tg yr}^{-1}$. These averages are very similar to those for the year 2005 and those corresponding to the zero bias in Fig. 13. The 1σ uncertainties on these figures are due to interannual variability alone.

The MACC-based deposition amounts above can be compared with other studies, going as far back as Galbally and Roy (1980) (see Table 2). The total land-based deposition in Galbally and Roy (1980) is similar to the present estimates but their oceanic deposition is five times as large. This may be due to the fact that at that time there were only coastal measurements of ozone uptake by seawater with larger deposition velocities than for the open ocean.

More recently, Hardacre et al. (2015) analysed monthly ozone dry deposition fluxes from 15 global chemistry transport models (not including UKCA) driven by meteorological fields for the year 2001. These models use Wesely's scheme (1989) for the deposition velocity calculation for both water and terrestrial surfaces. ACCESS-UKCA also uses Wesely's scheme for terrestrial surfaces. A comparison of observed

Table 2. Mean ozone dry deposition based on the MACC data for the years 2003–2012 ($\text{Tg O}_3 \text{ yr}^{-1}$)¹, and from other studies that also report the oceanic component. The uncertainties are $\pm 1\sigma$.

Method	Ocean			Land			Total		
	NH	SH	Global	NH	SH	Global	NH	SH	Global
Galbally and Roy (1980) ²	191	300	491	459	141	600	650	441	1091
Ganzeveld et al. (2009) ³	–	–	291.5	–	–	543.5	–	–	835
Hardacre et al. (2015) ⁴	–	–	340	–	–	638	646	332	978 ± 127
Present study	51.3	47.1	98.4 ± 30.0	469.6	154.8	624.4 ± 82.0	520.9	201.9	722.8 ± 87.3

¹ The ocean component excludes sea ice and coastal grid boxes (which are included in the land component) and on average covers 62.4 % of the Earth's surface. ² In Galbally and Roy (1980), the oceanic component includes ice and there is an uncertainty of $\pm 50\%$ in their estimates. ³ Average values from two model runs. ⁴ The oceanic component is based on the average of values from two different land-cover schemes, and the NH and SH components based on Catherine Hardacre (personal communication, 2017). NH: Northern Hemisphere; SH: Southern Hemisphere.

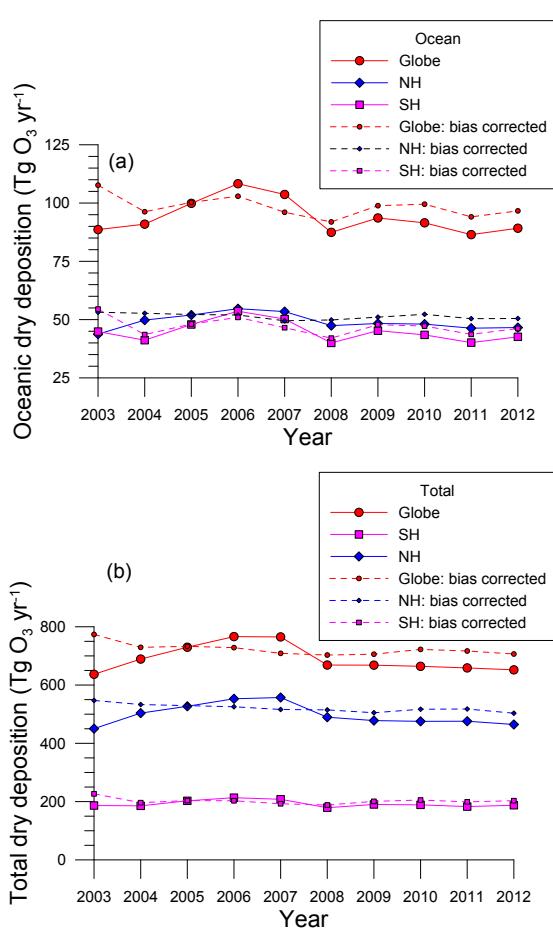

Figure 11. Annual variation in the dry deposition of ozone ($\text{Tg O}_3 \text{ yr}^{-1}$) obtained using the ACCESS-UKCA model (dotted lines) and the MACC reanalysis (solid lines): (a) the ocean component and (b) total. (NH: Northern Hemisphere; SH: Southern Hemisphere).

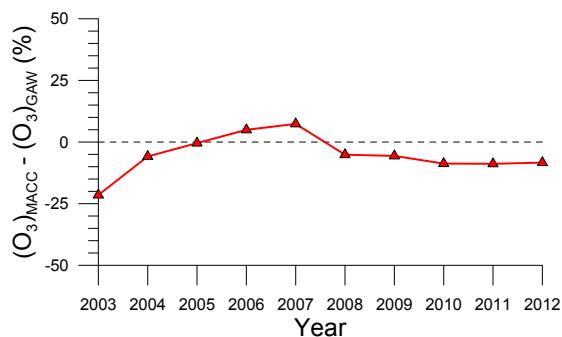

Figure 12. Annual averaged normalised median bias (%) of the MACC ozone reanalysis mixing ratios relative to the Global Atmosphere Watch (GAW) surface observations for the years 2003–2012.

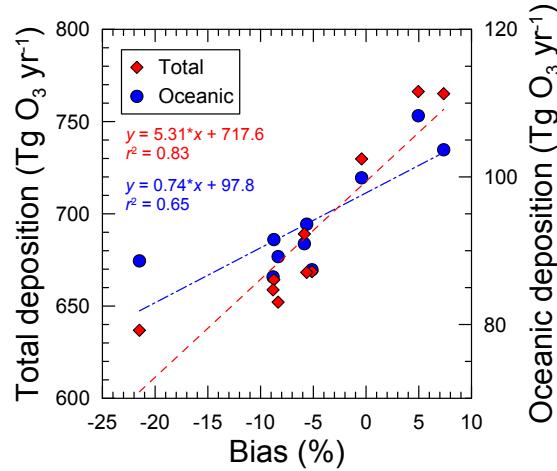

Figure 13. Scatter plot of annual averaged normalised median bias (%) in the MACC ozone reanalysis mixing ratios relative to the Global Atmosphere Watch (GAW) surface observations for the years 2003–2012 versus the total global deposition and total deposition to the ocean determined based on the MACC reanalysis. The best fit lines are also shown.

dry deposition fluxes with those obtained from the global chemistry transport models above for terrestrial surfaces is presented by Hardacre et al. (2015). These authors noted that differences in ozone dry deposition flux to the ocean, driven by small absolute differences in dry deposition velocity but with large areal coverage by the ocean, are the largest contributor to differences in the total global O₃ deposition compared to any other surface type. They determined that the mean total global deposition was $978 \pm 127 \text{ Tg O}_3 \text{ yr}^{-1}$, where the range corresponds to 1 standard deviation. By using two different land-cover schemes for partitioning fluxes, they determined that deposition to the ocean was in the range of 250–591 (average 361) Tg yr⁻¹ across the model ensemble using one land-cover scheme that had 71.2 % of the Earth's surface covered by water and 209–538 (average 319) Tg yr⁻¹ using the other that had 68.6 % of the global surface covered by water. The modelling study by Ganzeveld et al. (2009) points to an oceanic dry deposition estimate of 283–300 Tg yr⁻¹ and a global total of 833–837 Tg yr⁻¹ (Table 2). The oceanic deposition budgets in all these studies are more than 3 times larger than the 98.4 Tg yr⁻¹ value obtained in the present study. This much difference cannot be explained by the slightly lower fraction of the global surface covered by water in the present calculations (i.e. 62.4 %). The primary reason for this difference, as indicated earlier, is that the global chemistry transport models in these studies are all largely based on Wesely's (1989) deposition scheme, which uses a constant surface resistance for water. As shown by Luhar et al. (2017) the use of $r_c = 2200 \text{ s m}^{-1}$ overestimates open-ocean deposition velocity compared to the open-ocean measurements of Helmig et al. (2012) by a factor of 2 to 4 for cooler SSTs. The smaller oceanic deposition budget presented in this paper is consistent with these currently best available open-ocean measurements. The total deposition to non-water surfaces based on the MACC data is 624.4 Tg yr⁻¹, which is similar to 638 Tg yr⁻¹ obtained by Hardacre et al. (2015) (using an average oceanic deposition of 340 Tg yr⁻¹ in their calculations) and 600 Tg yr⁻¹ obtained by Galbally and Roy (1980).

There are other studies that report on the total global dry deposition. Stevenson et al. (2006) report an average global ozone dry deposition of $1003 \pm 200 \text{ Tg yr}^{-1}$ for the year 2000 based on 21 models. The average deposition calculated by Wild (2007) using 17 post-2000 modelling studies is $949 \pm 222 \text{ Tg yr}^{-1}$, whereas that reported by Young et al. (2013) for the year 2000 based on a subset of six models participating in the ACCMIP intercomparison study is $1094 \pm 264 \text{ Tg yr}^{-1}$. However, these studies do not report values of oceanic deposition separately.

It is clear from the comparison above that the land component of total deposition remains similar in all the studies (after subtracting an oceanic contribution of $\sim 300 \text{ Tg yr}^{-1}$ from the total in the previous studies). The new estimate of dry deposition to the ocean of $\sim 100 \text{ Tg O}_3 \text{ yr}^{-1}$ is approximately a third of the current model estimates. This reduction

corresponds to an approximately 67 % decrease in the modelled oceanic dry deposition and 20 % decrease in the modelled total dry deposition.

Based on a simple calculation involving the tropospheric ozone budgets given in IPCC (2013) following Young et al. (2013), we estimate that the reduction in the modelled dry deposition rate by $\sim 200 \text{ Tg O}_3 \text{ yr}^{-1}$ over the ocean presented here (with all other factors being unchanged) results in roughly a 5 % increase in modelled tropospheric ozone burden and an equivalent increase in tropospheric ozone lifetime. In the marine boundary layer at mid to high latitudes, the effect of the ozone increase would be expected to be larger.

5.3 Uncertainty in annual ozone dry deposition

The (1σ) uncertainty in the global ozone deposition of $1003 \pm 200 \text{ Tg yr}^{-1}$ reported by Stevenson et al. (2006), $949 \pm 222 \text{ Tg yr}^{-1}$ by Wild (2007), $1094 \pm 264 \text{ Tg yr}^{-1}$ by Young et al. (2013), and $978 \pm 127 \text{ Tg yr}^{-1}$ by Hardacre et al. (2015) based on multi-model runs is by and large all due to model-to-model variations. Here we attempt a comparable uncertainty estimate.

Our modelling yields an ozone deposition loss to the ocean of $98.4 \pm 4.5 \text{ Tg yr}^{-1}$ and a total global deposition of $722.8 \pm 20.9 \text{ Tg yr}^{-1}$, with the 1σ error bounds in these estimates only representing the 10-year interannual variability in the modelled deposition velocity and MACC concentration fields. These error bounds do not include any uncertainties that may arise due to the approximations and assumptions used in the deposition velocity (e.g. iodide concentration, reaction rate constant) or MACC ozone reanalysis methodologies.

In earlier discussion of the oceanic dry deposition velocity in Sect. 2.2 it was identified that calculations of the reaction-diffusion length scale ($l_m = \delta_m / c_0$) based on oceanic observations of iodide and SST give results varying between 24.0 and 1.2 μm for the SST range 2–33 °C, and it is 3 μm at 23 °C. In the subsequent work in this paper a value of 3 μm is used for the depth of the reaction-diffusion sublayer (δ_m). Considering Fig. 3c and d, the waterside deposition velocity varies by at most a factor of 2 for the range of variations in δ_m that lie between the two extreme physical limits of a one-layer diffusive model and a one-layer turbulent model. These limits implicitly encompass the uncertainties in the rate constant and iodide concentrations. Assuming these limits can be described as three-sigma, we estimate that the one-sigma uncertainty in δ_m is approximately $\pm 30\%$. This uncertainty can directly feed into the uncertainty of the global ozone deposition rates. Combining it with the 1σ error bounds in the MACC ozone reanalysis gives a combined relative uncertainty of $\pm 31\%$ or our total oceanic deposition of 98.4 Tg yr⁻¹ with an uncertainty $\pm 30.5 \text{ Tg yr}^{-1}$.

An alternate approach to estimate uncertainty for the oceanic component, which is the main focus here, is to con-

sider the scatter in the deposition velocity observations of Helmig et al. (2012) in Fig. 7, which show some large fluctuations in the v_d data that are not present in the modelled values. We take the difference between the amount of scatter in the v_d data and that in the modelled values as a measure of uncertainty that is not captured by the model. We call this difference residual uncertainty (σ_{vdr}), which we aim to account for. In order to quantify σ_{vdr} , four SST ranges, namely < 15 , $15\text{--}21$, $21\text{--}28$, and $> 28^\circ\text{C}$, which approximately correspond to the SST ranges of the cruise experiments shown in Fig. 7, were considered. For each SST range, the v_d data were detrended by fitting a linear v_d versus SST regression line and the variance (σ_{vdo}^2) of the detrended data was calculated. Similarly, the variance (σ_{vdm}^2) of the detrended modelled v_d values was calculated for the same SST range. Thus $\sigma_{vdr} = (\sigma_{vdo}^2 - \sigma_{vdm}^2)^{1/2}$, and its values were 0.0046, 0.0093, 0.0049, and 0.0056 cm s^{-1} for the SST ranges above, respectively.

To calculate the uncertainty in oceanic deposition flux due to σ_{vdr} , the 3 h modelled deposition velocity at each grid point was perturbed by $\pm\sigma_{vdr}$ (which is selected from one of the four values above depending on which SST range the SST at the grid point falls into) and then multiplied with the 3 h MACC ozone fields. This was performed for all 10 years, which yielded the uncertainty in the oceanic ozone deposition flux due to $\pm\sigma_{vdr}$ to be $\pm 30.0\text{ Tg yr}^{-1}$ (which includes the small interannual variability of $\pm 4.5\text{ Tg yr}^{-1}$ stated earlier).

Thus for our total oceanic deposition of 98.4 Tg yr^{-1} we have two uncertainty estimates of $\pm 30.5\text{ Tg yr}^{-1}$ based on the uncertainty in the deposition velocity model and the uncertainty $\pm 30.0\text{ Tg yr}^{-1}$ based on the random differences between the model and observations for the available data. While these independent estimates agree very well, the wider issue is that the world's oceans are under-sampled with regard to ozone uptake measurements; it cannot be assumed that the available measurements are a representative sample of the ozone uptake over the world's oceans and the uncertainties, consequently, are probably underestimates.

The total oceanic deposition and uncertainty estimates calculated here can be contrasted with the value $340.0 \pm 98.6\text{ Tg yr}^{-1}$ obtained by Hardacre et al. (2015). It is interesting to note that our mean and standard deviation are both approximately a third of the respective values obtained by Hardacre et al. (2015). There would also be uncertainty in the MACC ozone data apart from their interannual variability, which we have not considered.

With regards to the uncertainty in deposition to non-water surfaces, since our model uses the same Wesely (1989) deposition scheme as most other global models for such surfaces, we assume that the corresponding uncertainty would be similar to that in those models. Only Hardacre et al. (2015) report uncertainties in deposition fluxes to both water and non-water surfaces, with the latter calculated to be $\pm 80.0\text{ Tg yr}^{-1}$. This value when combined with the interannual variability

of $\pm 17.4\text{ Tg yr}^{-1}$ for non-water surfaces obtained here leads to a total uncertainty of $\pm 82.0\text{ Tg yr}^{-1}$ for such surfaces. Hence the total uncertainty combining this non-water component ($\pm 82.0\text{ Tg yr}^{-1}$) and the water component derived above ($\pm 30.0\text{ Tg yr}^{-1}$) is $\pm 87.3\text{ Tg yr}^{-1}$.

The global oceanic and total deposition fluxes with the revised uncertainty are 98.4 ± 30.0 and $722.8 \pm 87.3\text{ Tg yr}^{-1}$, respectively (Table 2). The reduction in the total uncertainty compared to Hardacre et al.'s (2015) value of $\pm 127\text{ Tg yr}^{-1}$ is due to the reduction in the magnitude of the water component of deposition flux.

6 Conclusions

The ocean-phase surface resistance term dominates over aerodynamic and atmospheric viscous sublayer resistances in commonly used parameterisations of ozone dry deposition velocity at the oceanic surface. Recent mechanistic schemes used to parameterise the oceanic surface resistance take into account the simultaneous effects of ozone solubility in water, waterside molecular diffusion and turbulent transfer, and first-order chemical reaction of ozone with dissolved iodide and other compounds. Luhar et al. (2017) formulated a semi-empirical scheme that described existing deposition velocity data well, but in order to compensate for the impact of over-estimation of turbulent transfer within the waterside viscous sublayer it put an artificial limit on the iodide concentration to a fixed depth of the order of a few micrometres from the water surface, whereas in reality iodide is present through the depth of the oceanic mixing layer. Here we presented a new analytical two-layer formulation for the oceanic surface resistance that avoids making this limiting assumption. Instead, it makes the valid assumption that the influence of turbulent transfer can be neglected compared to the influence of chemical reaction within the top layer of water that is of the order of the reaction-diffusion length scale (typically a few micrometres). In the water layer below, both chemical reaction and turbulent transfer act together and are accounted for. The new scheme has an asymptotic behaviour that is consistent with the current limits of ozone dry deposition when either chemical reaction or turbulent transfer dominate. When compared against the available observed deposition velocity dependencies on sea surface temperature, the performance of the new two-layer dry deposition scheme as re-calculated within the global chemistry-climate model ACCESS-UKCA (at UM vn8.4) was found to be satisfactory with the inclusion of only the aqueous iodide-O₃ reaction. However, additional ocean-based measurements are needed for further development and evaluation of ozone deposition parameterisations with an aim of reducing uncertainty in ozone modelling.

By using the 3 h MACC reanalysis for ozone concentration for the years 2003–2012 and the corresponding modelled 3 h deposition velocity values using the new dry depo-

sition scheme for the ocean presented here and the default scheme for the other surface types, the deposition budget has been calculated and quantified. The annual ozone deposition value is $722.8 \pm 87.3 \text{ Tg O}_3 \text{ yr}^{-1}$ for the globe and $98.4 \pm 30.0 \text{ Tg O}_3 \text{ yr}^{-1}$ for the ocean. This new estimate of oceanic dry deposition represents a reduction of approximately 67 % over the current estimates of oceanic deposition. This reduction leads to a 20 % decrease in the modelled total global dry deposition, and with all other factors being unchanged, to an increase of approximately 5 % in the modelled tropospheric ozone burden and an equivalent increase in tropospheric ozone lifetime.

Data availability. The source of the MACC ozone reanalysis data is cited in the text. The deposition velocity output from the ACCESS-UKCA global model (in NetCDF format) and the various processed ozone deposition parameter values (in ASCII format) can be made available by contacting the corresponding author (Ashok Luhar: ashok.luhar@csiro.au).

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. This research was undertaken with the assistance of resources and services from the National Computational Infrastructure (NCI), which is supported by the Australian government. Luke Abraham of the University of Cambridge and Fiona O'Connor and Mohit Dalvi of the UK Met Office are thanked for their assistance with the UM-UKCA model. Catherine Hardacre is acknowledged for providing additional details of their published deposition work. We are indebted to Ludovic Bariteau for kindly supplying data related to their published work. ERA-Interim data from the European Centre for Medium-Range Weather Forecasts and the ozone reanalysis data from the European MACC program were used in this research. We thank the anonymous reviewers for their helpful comments.
